Abstract. We propose a new algorithm and architecture for performing divisions in residue number systems. Our algorithm is suitable for residue number systems with large moduli, with the aim of manipulating very large integers on a parallel computer or a special-purpose architecture. The two basic features of our algorithm are the use of a high-radix division method, and the use of a floating-point arithmetic that should run in parallel with the modular arithmetic.

1. Introduction

The context of this work is the manipulation of huge numbers (say, more than one thousand bits). This topic concerns various fields, e.g., computer algebra, cryptography, and algorithmic geometry. Residue number systems (abbreviated as RNS) are good number representations for these domains [1, 2]. We propose a new division algorithm for Residue Number Systems. Our algorithm has been designed for applications where manipulation of huge numbers is required. Conventional RNS VLSI architectures [3, 4] can be easily adapted in order to use this algorithm.

A Residue Number System (RNS) uses a set of moduli \( (m_1, ..., m_n) \) that are relatively prime integers (i.e., \( \gcd(m_i, m_j) = 1 \) if \( i \neq j \)). A number \( X \) is represented by the residues

\[ X \equiv x_i \pmod{m_i}, \quad 0 \leq x_i < m_i. \]

The very origin of such systems is quite old: it goes back to the well-known Chinese Remainder Theorem (CRT) [5]. In an RNS, additions, subtractions and multiplications are straightforwardly performed in parallel (provided that no overflow occurs), using separate ALU's; this allows division-free RNS computations to be quickly completed [6, 7, 8]. Unfortunately, divisions and comparisons look difficult to perform in a residue number system [9, 10].

In the following, the set \( (m_1, ..., m_n) \) of relatively prime integers is called the RNS base, and to simplify we assume that the \( m_i \)'s are prime numbers.

The CRT shows that for any \( n \)-tuple \( (x_1, ..., x_n) \), \( 0 \leq x_i < m_i \), there exists an unique integer \( X \), \( 0 \leq X < M = \prod_{i=1}^{n} m_i \), such that \( (x_1, ..., x_n) \) represents \( X \). The CRT also gives an algorithm that computes \( X \).

In Section 2, we introduce a “weighted representation”, that makes it possible to know the first significant digits and the order of magnitude of a number represented in an RNS. We also give an architecture for computing this representation from the RNS representation.

Using this “weighted representation”, we present a new algorithm for RNS division in section 3. This algorithm gives the quotient and the remainder of the Euclidean division of two RNS numbers.

In Section 4, we analyze this algorithm and its performances.

In the last section, we compare our method to recently published algorithms.

2. Weighted RNS arithmetic

As outlined above, our algorithm uses a “weighted arithmetic”, based on the combination of an RNS arithmetic and a floating-point-like arithmetic. The basic idea behind this — keeping the order of magnitude of RNS numbers — is not new. Similar ideas have been previously suggested [3, 10], in order to detect overflows. The new aspect is that we use this for comparisons and quotient-digit estimations.

We introduce a Floating-Point Like (FPL) notation which is associated with the residue notation and that makes it possible to know the order of magnitude of a number from its RNS representation.

2.1. The FPL representation

Our Floating-Point Like representation is deduced from the following theorem.

**Theorem 1.** Let \( (m_1, \ldots, m_n) \) be an RNS base.

Let \( \beta \geq 2 \) and \( \mu \geq 1 \) be integers such that

\[
\beta^{\mu-1} \leq m_i < \beta^\mu, \quad i = 1 \ldots n.
\]

We assume that \( M = \prod_{i=1}^{n} m_i \) satisfies

\[
0 \leq X < M \times \beta^{-1}.
\]

Let \( X \) be an integer, whose RNS representation is \( (x_1, \ldots, x_n) \) in the RNS base \( (m_1, \ldots, m_n) \). We assume that the \( x_i \)'s are represented in radix \( \beta \). If we know \( X_{\text{exp}} \) such that

\[
\beta^{-\ell+1} \leq X \times \beta^{X_{\text{exp}}} \leq \beta^{-1}
\]

with \( \ell = \lceil \log_\beta n \rceil + 1 \), then we can compute a \( \mu \)-digit approximation \( X_{\text{frac}} \) of \( X \times \beta^{X_{\text{exp}}} \times \beta^{\ell} \), using \( 2\mu \) digit integers only. This approximation \( X_{\text{frac}} \) satisfies:

\[
X_{\text{frac}} \leq \frac{X \times \beta^{X_{\text{exp}}+\mu}}{M} < X_{\text{frac}} + \beta^\mu.
\]

In Theorem 1, \( X_{\text{exp}} \) is a rather small number \( (X_{\text{exp}} \approx n \times \mu) \), such that \( X \times \beta^{X_{\text{exp}}} \) is close to \( M \). The integer \( X_{\text{exp}} \) indicates the order of magnitude of \( X \) relatively to \( M \): the larger is \( X \), the smaller is \( X_{\text{exp}} \). Remember that \( X_{\text{frac}} \) is a \( \mu \)-digit number. We have:

\[
X_{\text{frac}} \times \beta^{-X_{\text{exp}}} \simeq X \left( \frac{\beta^\mu}{M} \right)
\]

Therefore \( (X_{\text{exp}}, X_{\text{frac}}) \) can be viewed as a (weighted) “floating-point representation” of \( X \).

**Definition 1.** The couple \( (X_{\text{exp}}, X_{\text{frac}}) \) is called the Floating-Point Like (FPL) representation of the RNS number \( X \) (\( X_{\text{exp}} \) is the “exponent” and \( X_{\text{frac}} \) is the “fraction” of this representation).

There may be several values of \( (X_{\text{exp}}, X_{\text{frac}}) \) that satisfy the requirement of the above definition. The most accurate representation is the one with the largest value of the fraction — exactly as in conventional floating point arithmetic — and consequently with the largest value of \( X_{\text{exp}} \).

2.2. Computation with FPL arithmetic

The FPL representation is manipulated in parallel with the RNS representation, using
the usual floating-point algorithm for addition, and a slightly modified one for multiplication. In order to compute $X \times Y$, $(X_{\text{frac}} \times \beta^{-\text{Xexp}}) \times (Y_{\text{frac}} \times \beta^{-\text{Yexp}})$ is first computed using the usual floating-point algorithm (that is, multiplication of the fractions and addition of the exponents), then the result is multiplied by a floating-point approximation of $\frac{M}{\beta^\mu}$ to take into account the “weight” $\frac{\mu}{\beta^\mu}$ that appears in (3).

Generally, the FPL representations suffice for comparing two numbers. However, if the numbers that are being compared are very close, or if, after many computations, the FPL representations becomes too inaccurate. Then it is necessary to “refresh” them (i.e., re-compute them from the RNS representations). This reconstruction is performed when the error on the FPL representations becomes so large that a comparison is impossible. A way to detect this is to implement an interval arithmetic with the FPL representations. In this case this reconstruction can be performed in two steps. Firstly, a “good” $X_{\text{exp}}$ is determined. Secondly, the corresponding $X_{\text{frac}}$ is computed. In the following, we show how to construct and how to “refresh” the FPL representation of an RNS number.

2.3. Construction of the FPL representation

In order to compute or to refresh the FPL representation of an RNS number $X$, the Mixed-Radix System associated with the RNS-base $(m_1, \ldots, m_n)$ can be used [5], but this solution seems intrinsically sequential. The formula that appears in the proof of the CRT looks much more parallelizable. This relation is:

$$X \equiv \sum_{i=1}^{n} x_i \times (M_i)_{m_i}^{-1} \times M_i \pmod{M}$$

with $M_i = \frac{M}{m_i}$ and $(M_i)_{m_i}^{-1} \times M_i \equiv 1 \pmod{m_i}$.

We can notice that,

$$\sum_{i=1}^{n} x_i \times (M_i)_{m_i}^{-1} \times M_i = \left( \sum_{i=1}^{n} x_i \times \frac{(M_i)_{m_i}^{-1}}{m_i} \right) \times M$$

So, $\frac{X}{M}$ is the fractional part of:

$$\left( \sum_{i=1}^{n} x_i \times \frac{(M_i)_{m_i}^{-1}}{m_i} \right)$$

This construction is characterized by the fact that all the computations are performed with integers. Since the evaluation is done modulo $M$, we just have to manipulate the fractional part of each term $x_i \times \frac{(M_i)_{m_i}^{-1}}{m_i}$, and the fractional part of the sum $\sum_{i=1}^{n} x_i \times \frac{(M_i)_{m_i}^{-1}}{m_i}$ in order to compute $X_{\text{frac}}$.

2.3.1. Proof of Theorem 1: construction of $X_{\text{frac}}$

We want to perform this computation with $\mu$-digit integers. During this computation only the first $\mu$ digits of the fractional part are taken into account.

According to the conditions of Theorem 1, we know $X_{\text{exp}}$ such that,

$$\beta^{-\mu+\ell+1} \leq \frac{X \times \beta^{X_{\text{exp}}}}{M} < \beta^{-1}$$

Then there is at least one significant digit in the first $\mu - \ell$ digits of the fractional part of $\left( X \times \beta^{X_{\text{exp}}} \right) / M$. We note $X = X \times \beta^{X_{\text{exp}}}$ and $(\bar{x}_1, \ldots, \bar{x}_n)$ the RNS representation of $X$.

We can first remark that for each integer $i, 1 \leq i \leq n$, we have

$$\beta^{-\mu} \times \frac{(M_i)_{m_i}^{-1}}{m_i} < 1$$

Define $\Omega_i$ as the integer constituted by the first $2\mu$ digits of the fractional part of $\frac{(M_i)_{m_i}^{-1}}{m_i}$:

$$\Omega_i = \left[ \frac{(M_i)_{m_i}^{-1}}{m_i} \times \beta^{\mu} \right]$$

$\frac{(M_i)_{m_i}^{-1}}{m_i} = \begin{array}{l} 0 \cdot \mu \text{-digit number} \quad \mu \text{-digit number} \ldots \\ \Omega_i \text{ is a } 2\mu \text{-digit number} \end{array}$

We have,

$$\frac{(M_i)_{m_i}^{-1}}{m_i} \times \beta^{\mu} - 1 < \Omega_i \leq \frac{(M_i)_{m_i}^{-1}}{m_i} \times \beta^{\mu}$$
The terms \( \Omega_i \) are precomputed and stored constants. Now, let us multiply the \( \mu \)-digit integer \( \bar{x}_i \) by \( \Omega_i \). The result is a \( 3\mu \)-digit integer. We note \( \alpha_i \) the integer whose digits are the first \( \mu \) digits of the fractional part of \( \bar{x}_i \times \Omega_i \times \beta^{-2\mu} \):

\[
\alpha_i = \left[ \bar{x}_i \times \Omega_i \times \beta^{-\mu} \right] = \left[ \bar{x}_i \times \Omega_i \times \beta^{-2\mu} \right] \times \beta^\mu
\]

We have,

\[
\bar{x}_i \times \Omega_i \times \beta^{-\mu} - 1 < \alpha_i + \left[ \bar{x}_i \times \Omega_i \times \beta^{-2\mu} \right] \times \beta^\mu \leq \bar{x}_i \times \Omega_i \times \beta^{-\mu}
\]

From (5), we deduce,

\[
\bar{x}_i \times \left( \frac{M_i}{m_i} \right)^{-1} \times \beta^\mu = \bar{x}_i \times \beta^{-\mu} - 1 < \alpha_i + \left[ \bar{x}_i \times \Omega_i \times \beta^{-2\mu} \right] \times \beta^\mu \leq \bar{x}_i \times \left( \frac{M_i}{m_i} \right)^{-1} \times \beta^\mu
\]

Define \( \sigma \) as the integer whose digits are the first \( \mu - \ell \) digits of the fractional part of \( \sum_{i=1}^{n} \alpha_i \), followed by \( \ell \) zeros, that is:

\[
\sigma = \left[ \sum_{i=1}^{n} \alpha_i \times \beta^{-\ell} \right] \times \beta^\ell - \left[ \sum_{i=1}^{n} \alpha_i \times \beta^{-\mu} \right] \times \beta^\mu
\]

The least \( \ell \) significant digits of \( \sigma \) are set to 0 in order to compensate for the error committed when computing \( \sum_{i=1}^{n} \alpha_i \). This truncation suffices to satisfy (2).

Thus,

\[
\sum_{i=1}^{n} \alpha_i - \beta^\ell < \sigma + \left[ \sum_{i=1}^{n} \alpha_i \times \beta^{-\mu} \right] \times \beta^\mu \leq \sum_{i=1}^{n} \alpha_i
\]

(7)

So, we deduce from (6), (7) and (4) that:

\[
X \times \beta^\mu - \sum_{i=1}^{n} \bar{x}_i \times \beta^{-\mu} \times M - n \times M < \sigma \times M \leq X \times \beta^\mu
\]

Thus,

\[
X \times \beta^\mu - 2 \times n \times M < \sigma \times M \leq X \times \beta^\mu
\]

Using the definition of \( \ell \) we can conclude that,

\[
X \times \beta^\mu - \beta^\ell \times M < \sigma \times M \leq X \times \beta^\mu
\]

This gives:

\[
\sigma \leq \frac{X \beta^\mu}{M} < \sigma + \beta^\ell
\]

(8)

Remark With regard to equations (2) and (8), if \( \sigma \neq 0 \) then we can take \( X_{\text{frac}} = \sigma \). But if \( \sigma = 0 \), this means that \( X \) is small compared to \( M \) (\( X \leq M \beta^{-\ell+\epsilon+1} \)). In such a case, we have to start the process again with an increased value of \( X_{\text{exp}} \) that makes \( X \) closer to \( M \).

2.3.2. Construction of \( X_{\text{exp}} \) If \( X \) is small compared to \( M \), then \( \sigma \) is too small to be computed accurately, and we need to make \( X \) larger. Since the order of magnitude of \( X \) is unknown, we have to proceed in a stepwise fashion: we multiply it (in the RNS system) by \( \beta^{\ell-\mu} \) and try to convert it from the RNS to the FPL system at each step, until \( \sigma \) becomes significant. Of course \( \mu - \ell \) is added to \( X_{\text{exp}} \) at each step. After this, \( \sigma \) is significant and the order of magnitude of \( X \) is known.

As a matter of fact, even if \( \sigma \neq 0 \), if \( \sigma \) is small compared to \( \beta^\mu \), it may be advantageous to multiply (in the RNS system) \( X \) by \( \beta^{\ell} \), where \( \ell \) is such that \( \beta^{-\ell} \leq \sigma \times \beta^\ell < \beta^\mu \), and to start the process again, to get a much more accurate FPL representation. The worst case takes \( \left[ \log_\beta \frac{M}{\nu - \ell} \right] \) steps to compute the correct \( X_{\text{exp}} \) where

\[
\beta^\ell \leq M < \beta^{\ell+1}
\]
**Example 1.**

We consider the base: \( \{65437,65447,65449,65479,65497\} \)

\[
M = 12020972018631191837293 \quad \text{and} \quad \mu = 16 \quad \text{in} \quad \text{radix} \ 2.
\]

\[
M_i = \begin{cases} 
M_0 = 18370298177117398289 \\
M_1 = 18367491280211945419 \\
M_2 = 18366930083750128357 \\
M_3 = 18358514971456973867 \\
M_4 = 1835340665282089409 
\end{cases}
\]

\[
\Omega_i = \begin{cases} 
\Omega_0 = 30622536088 \\
\Omega_1 = 2923264766 \\
\Omega_2 = 2335264193 \\
\Omega_3 = 3837300181 \\
\Omega_4 = 720046657 
\end{cases}
\]

Assume \( X = 1282205882000084821 \). We have \( X_{\text{RNS}} = \{40715,64825,36443,60989,5521\} \)

**First step** \( X_{\text{exp}} = 0 \). This gives

\[
\begin{array}{c|c|c|c}
\text{Integer part} & \alpha_i & \text{Err.} \\
\hline
x_0 \times \Omega_0 & 1100101100111 & \sigma \\
x_1 \times \Omega_1 & 10101001001111 & \sigma \\
x_2 \times \Omega_2 & 10011010101111 & \sigma \\
x_3 \times \Omega_3 & 1001010011011111 & \sigma \\
x_4 \times \Omega_4 & 111010010101100111 & \sigma \\
\hline
\text{Sum} : & 1100100111111111 & \sigma \\
\hline
\end{array}
\]

Finally, according to the previous remark, we get \( \sigma = 0 \) with \( X_{\text{exp}} = 0 \). This is an insignificant value because \( X \) is small compared to \( M \). \( X_{\text{exp}} \) should be larger. Note that \( X_{\text{frac}} = 65520, X_{\text{exp}} = 0 \) corresponds to the FPL representation of the number 12018037210538607487298.

We will add \( \mu - \ell = 12 \) to \( X_{\text{exp}} \) at each step until \( \sigma \) is significant.

**Second step** \( X_{\text{exp}} = 12 \). This gives

\[
\begin{array}{c|c|c|c}
\text{Integer part} & \alpha_i & \text{Err.} \\
\hline
x_0 \times \Omega_0 & 11001011001111111111111111 & \sigma \\
x_1 \times \Omega_1 & 10101001001111111111111111 & \sigma \\
x_2 \times \Omega_2 & 10011010101111111111111111 & \sigma \\
x_3 \times \Omega_3 & 10010100110111111111111111 & \sigma \\
x_4 \times \Omega_4 & 111010010101100111 & \sigma \\
\hline
\text{Sum} : & 1100100111111111 & \sigma \\
\hline
\end{array}
\]

We finally obtain the FPL representation of \( X \):

\( X_{\text{frac}} = 18320 \) and \( X_{\text{exp}} = 18 \). We can verify according to Theorem 1 that:

\[
X_{\text{frac}} \leq \frac{X \times \beta^{X_{\text{exp}}+\mu}}{M} < X_{\text{frac}} + \beta^{\ell}
\]

with

\[
\frac{X \times \beta^{X_{\text{exp}}+\mu}}{M} = 18324 \quad \text{and} \quad X_{\text{frac}} + \beta^{\ell} = 18336
\]
2.4. An architecture for implementing the refreshment

The implementation uses $n \mu$-digit Arithmetic Units (AUs) and an FPL unit, which are connected to each other with a $\mu$-digit bus composed of sub-buses connected by gates, to realize of a binary tree for the evaluation of $\sigma$ and $X_{\text{frac}}$ in an $O(\log_2 n)$ computation time (figure 1).

Each AU has its own registers and memory that contain $m_i$, $\Omega_i$ and variables like $x_i$, $x_2$ or the partial value of $\sigma$. Such a unit is a $\mu$-digit adder with a control part that can perform specific additions to compute $\alpha_2$ and $\sigma$ (additions with no overflow control: the overflows correspond to the integer part), and addition and multiplication modulo($m_i$). The control part of each unit can be commanded by a single sequencer with instructions in a ROM for the different operations.

So the minimal functionalities of an AU-unit are:

- 7 $\mu$-digit Registers for the variables $m_i$, $\Omega_i$, $x_i$, $\alpha_2$ and buffers.
- One $\mu \times \mu$ multiplier, which computes the higher and the lower parts of the product in two $\mu$-digit registers.
- One $\mu$-digit adder

Evaluation of $\sigma$:

Initialization

Step $= k$

All gates are closed (no connection)

If $k \neq 0$ then

gates $k-1$ open the connections

$AU \ #(2n + 1)2^k$ sends to $AU \ #(2n)2^k$

$AU \ #(2n)2^k$ computes partial $\sigma$

Fig. 1. Architecture of the implementation
So we can propose an architecture similar to the normalizer part of the VLSI architecture presented in [3].

All the manipulated numbers are positive, so it is easy to consider only the least significant part knowing that the first significant digit must be positive. To have an idea of the size (which is \(O(n \times \mu)\)), a Borrow-Save implementation (radix \(\beta = 2\) and digits in \(\{-1, 0, 1\}\)) with \(\mu = 16\) and \(n = 64\) (which gives \(M \approx 2^{1000}\)) uses around 50,000 transistors for the arithmetic part. So it is possible to implement other operations in hardware, for example a modular multiplication [17].

The FPL-unit controls the bus routing and schedules the computations performed by all the units. With regard to the iteration step the FPL-unit commands the communications between the sub-buses (figure 1).

3. An RNS division algorithm

Let \(X_{RNS}\) be the RNS representation of \(X\). From two numbers \(X_{RNS}\) and \(Y_{RNS}\), we wish to compute to numbers \(Q_{RNS}\) and \(R_{RNS}\) satisfying:

\[
X_{RNS} = Q_{RNS} \times Y_{RNS} + R_{RNS}
\]

with \(0 \leq R_{RNS} < Y_{RNS}\).

Our algorithm is derived from a classic high radix division algorithm, where \(Q\) and \(R\) are respectively initialized to 0 and \(X\). The main iteration of this algorithm consists in determining \(D = D_m \times \beta^{D_e}\), (where \(D_m\) can be viewed as a high-radix quotient digit) so that \(X = (D+Q) \times Y + R\). After each step \(D\) is added to the quotient \(Q\), and \(D \times Y\) is subtracted from \(R\). This iteration is performed until the remainder is less than the divisor. All the computations in the division process are performed in RNS.

The determination \(D\) and the comparison between \(R\) and \(Y\) are performed using the FPL representation of the operands. The FPL-unit broadcasts \(D_m\) and \(D_e\) to the AU-units that construct \(D_{RNS}\). Each residue \(d_i\) is computed in the corresponding AU-unit. Next, the RNS computation of \(Q_{RNS}\) and \(R_{RNS}\) is performed. Each AU-unit determines the corresponding residues \(q_i\) and \(r_i\).

The last comparison is performed in the mixed-radix system. We denote \(X_{MRS} = (a_1, \ldots, a_n)\) the representation of \(X\) in the Mixed-Radix system associated with the RNS-base \((m_1, \ldots, m_n)\). That is to say,

\[
X = a_1 + a_2 m_1 + a_3 m_1 m_2 + \cdots + a_n m_1 m_2 m_3 \cdots m_{n-1}
\]

with \(0 \leq a_i \leq m_i - 1\).

We first give the algorithm, and we will give comments, examples and proofs afterwards.

1. Pre computing:
2. Construction of \((X_{\text{exp}}, X_{\text{frac}})\) and \((Y_{\text{exp}}, Y_{\text{frac}})\)
3. Construction of \(Y_{MRS}\)
4. Initialization:
5. \(R_{RNS} \leftarrow X_{RNS}\)
6. \((R_{\text{exp}}, R_{\text{frac}}) \leftarrow (X_{\text{exp}}, X_{\text{frac}})\)
7. \(Y_{ff} \leftarrow Y_{\text{frac}} + \beta^e\)
8. \(Q_{RNS} \leftarrow 0\)
9. loop:
10. while \(R_{\text{exp}} < Y_{\text{exp}}\) or \((R_{\text{frac}} \geq Y_{ff}\) and \(R_{\text{exp}} = Y_{\text{exp}})\)
11. if \(R_{\text{frac}} \neq 0\) then
12. \((D_m, D_e)\) is computed in the FPL-unit
13. The FPL-unit broadcasts \((D_m, D_e)\) to the AU-units
14. The AU-units compute \(D_{RNS}\)
15. \(R_{RNS} \leftarrow R_{RNS} - Y_{RNS} \times D_{RNS}\)
16. \(Q_{RNS} \leftarrow Q_{RNS} + D_{RNS}\)
17. if \( Y_{\text{exp}} - R_{\text{exp}} \geq \mu - \ell - 2 \) then
18. \( R_{\text{exp}} \leftarrow R_{\text{exp}} + \mu - \ell - 2 \)  
(in FPL-units)
19. else \( R_{\text{exp}} \leftarrow Y_{\text{exp}} \)  
(in FPL-units)
20. Reconstruct \( R_{\text{inc}} \)  
(in FPL-units)
21. end:
22. if \( R_{MRS} \geq Y_{MRS} \) then
23. \( R_{RNS} \leftarrow R_{RNS} - Y_{RNS} \)  
(in AU-units)
24. \( Q_{RNS} \leftarrow Q_{RNS} + 1_{RNS} \)  
(in AU-units)

**Remarks**

- All the RNS operations are performed in the AU-units.
- All the tests and operations with FPL notations are performed in the FPL-unit.
- During the computation, the FPL-unit controls the system.
- In order to get an upper bound on \( D \), we use \( Y_{ff} \), which is an upper bound of \( Y_{\text{inc}} \) according to (2). Thus \( R \) remains positive.

- The reconstruction of \( R_{\text{inc}} \) is performed according to the method depicted in the previous section.
- The test \( R_{MRS} \geq Y_{MRS} \) is performed using a conventional mixed-radix conversion of \( R_{RNS} \), and a mixed-radix comparison with the precomputed value of \( Y_{MRS} \) [3].

**Computation of \( D_m \) and \( D_e \) in the FPL unit** The evaluation of two numbers \( D_m \) and \( D_e \) such that \( D = D_m \times \beta^D_e \) is performed in the FPL-unit using the following algorithm, that requires integer operations only.

1. Compute \( R_n \) such that \( \beta^{-1} < \frac{R_{\text{inc}} \times \beta^{R_n}}{Y_{ff}} < \beta \)  
(Normalization)
2. If \( Y_{\text{exp}} - R_{\text{exp}} - R_n \geq 0 \) then
3. \( R_s \leftarrow \text{inf}(Y_{\text{exp}} - R_{\text{exp}} - R_n, \mu - 1) \)  
(Division of the normalized fraction)
4. \( D_m \leftarrow \left\lfloor \frac{R_{\text{inc}} \times \beta^{R_n + R_s}}{Y_{ff}} \right\rfloor \)  
(Computation of the exponent)
5. \( D_e \leftarrow Y_{\text{exp}} - R_{\text{exp}} - R_n - R_s \)
6. else
7. \( D_m \leftarrow 1 \)
8. \( D_e \leftarrow 0 \)

**Remarks** Firstly, \( D_m \) is a \((\mu - 1)\)-digit number and then \( D_m \equiv D_n \) modulo \((m_i)\) for each \( 1 \leq i \leq n \). Secondly, \( D \) is at least equal to 1 since \( R > Y \). This remark is useful for the last iteration.

**Computation of \( D \) modulo \((m_i)\) in the \( i \)-th Arithmetic Unit (AU)** The FPL unit broadcasts \((D_m, D_e)\) to each arithmetic unit. The \( i \)th unit computes \( d_i \) such that \( D \equiv d_i \) modulo \((m_i)\). \( D_e \) is less than \( n \times \mu \). The residues \( d_i \) can be computed in different ways.

If \( n \times \mu < \beta^\mu \) then \( D_e \) can be represented by a \( \mu \)-digit number. The latter assumption is often satisfied: for example, if \( \beta = 2, \mu = 16 \) that corresponds to \( n < 2^{12} \). The residue of \( \beta^{D_e} \) modulo \( m_i \) can be read in a local table if \( \mu \) is not too large. For example, if \( \beta = 2 \) and \( \mu = 16 \) then the size of the look-up tables is 2Kb. The computation of \( d_i \) can be performed in one step.
Otherwise, $D_e$ can be decomposed in radix $\beta^e$. In this case we can use $\log_\beta(n \times \mu)$ look-up tables of size $\beta^e \times \mu$. Thus the residue of $\beta^D_e$ modulo $m_i$ is computed with at most $\log_\beta(n \times \mu)$ look-up table accesses and $\log_\beta(n \times \mu) - 1$ modular multiplications. If $\beta^e$ is close to $\mu$, then $d_i$ is computed with at most $\log_\beta n + 1$ look-up table accesses and $\log_\beta n + 1$ modular multiplications.

**Example 2.**

We consider the base:

$$\{65437, 65447, 65449, 65479, 65497\}$$

which gives $\mu = 16$, in radix 2. In this example the Euclidean division of $X$ by $Y$ is performed in RNS:

$$X = 1282205882000084821$$
$$X_{\text{frac}} = 18320$$
$$X_{\text{exp}} = 18$$

$$Y = 135$$
$$Y_{\text{frac}} = 17376$$
$$Y_{\text{exp}} = 71$$
$$Y_{\text{ff}} = 17392$$

$(X_{\text{frac}}, X_{\text{exp}})$ and $(Y_{\text{frac}}, Y_{\text{exp}})$ are the representations of $X$ and $Y$ in the FPL system. Note that the high-radix division is performed with $Y_{\text{ff}}$ — which is an upper bound of the divisor — instead of $Y_{\text{frac}}$ in order to obtain a positive remainder.

**Step 1**

$$Y_{\text{exp}} - R_{\text{exp}} = 53 \text{ and } FD = 1$$

$$\frac{R_{\text{frac}}}{Y_{\text{ff}}} = 9487804182776850.0$$

$$D = 9487685836079104$$
$$Q = 9487685836079104$$
$$R = 1368294129405781$$
$$Rk = 28$$
$$R_{\text{frac}} = 20016$$

**Step 2**

$$Y_{\text{exp}} - R_{\text{exp}} = 43 \text{ and } FD = 1$$

$$\frac{R_{\text{frac}}}{Y_{\text{ff}}} = 10123194453414980$$

$$D = 1012701045760$$
$$Q = 949780537124864$$
$$R = 172948828181$$
$$Rk = 38$$
$$R_{\text{frac}} = 25904$$

**Step 3**

$$Y_{\text{exp}} - R_{\text{exp}} = 33 \text{ and } FD = 1$$

$$\frac{R_{\text{frac}}}{Y_{\text{ff}}} = 12794024015.131556$$

$$D = 12793675776$$
$$Q = 9497821330800640$$
$$R = 2341998421$$
$$Rk = 48$$
$$R_{\text{frac}} = 35936$$

**Step 4**

$$Y_{\text{exp}} - R_{\text{exp}} = 23 \text{ and } FD = 1$$

$$\frac{R_{\text{frac}}}{Y_{\text{ff}}} = 17332855.468353$$

$$D = 17332224$$
$$Q = 9497821348132864$$
$$R = 2148181$$
$$Rk = 58$$
$$R_{\text{frac}} = 33744$$

**Step 5**

$$Y_{\text{exp}} - R_{\text{exp}} = 13 \text{ and } FD = 1$$

$$\frac{R_{\text{frac}}}{Y_{\text{ff}}} = 15894.137994$$

$$D = 15894$$
$$Q = 9497821348148758$$
$$R = 2491$$
$$Rk = 68$$
$$R_{\text{frac}} = 40064$$

**Step 6**

$$Y_{\text{exp}} - R_{\text{exp}} = 3 \text{ and } FD = 0$$

$$\frac{R_{\text{frac}}}{Y_{\text{ff}}} = 18.428703$$

$$D = 18$$
$$Q = 9497821348148776$$
\( R = 61 \)
\( Rk = 71 \)
\( R_{\text{frac}} = 40064 \)

No extra correcting step is required, because \( R \) is less than \( Y \), and
\[
X = Q \times Y + R
\]
with
\[
\begin{align*}
X & = 1282205882000084821 \\
Y & = 135 \\
Q & = 9497821348148776 \\
R & = 61
\end{align*}
\]

4. Analysis of the RNS division algorithm

This algorithm is very similar to high-radix, SRT-like, division algorithms. At each step, a new radix-\( \beta^{\log_{\beta} n} \) digit of the quotient is computed. The difference lies in the fact that the remainders are computed in the Residue Number System and converted to the FPL system.

**Theorem 2.** If \( \mu > \ell + 2 \) then from two numbers \( X_{\text{RNS}} \) and \( Y_{\text{RNS}} \), Algorithm 0 gives \( Q_{\text{RNS}} \) and \( R_{\text{RNS}} \) such that:

\[
X_{\text{RNS}} = Q_{\text{RNS}} \times Y_{\text{RNS}} + R_{\text{RNS}}
\]

with \( 0 \leq R_{\text{RNS}} < Y_{\text{RNS}} \)

**Proof of the “while” loop:** \( R_{\text{exp}} \) decreases to \( Y_{\text{exp}} \)

Let us remind the notations:

\[
\begin{align*}
\beta^X & < X < \beta^{X+1} \\
\beta^Y & \leq Y < \beta^{Y+1} \\
\beta^M & \leq M < \beta^{\mu+1} \\
\ell & = [\log_{\beta} n] + 1
\end{align*}
\]

We have,
\[
\frac{R}{M} \beta^{\ell+\mu-\text{exp}} < \beta^\ell < \frac{R_{\text{frac}}}{M} \beta^{\ell+\text{exp}}
\]
and,
\[
\frac{Y}{M} \beta^{\ell+\text{exp}} \leq Y_{\text{ff}} < \frac{Y}{M} \beta^{\ell+\text{exp}} + \beta^\ell
\]

Thus,
\[
\frac{R \beta^{\ell+\text{exp}} - M \beta^\ell}{Y \beta^{\ell+\text{exp}} + M \beta^\ell} < \frac{R_{\text{frac}}}{Y_{\text{ff}}} \leq \frac{R \beta^{\text{exp}}}{Y \beta^{\text{exp}}}
\]
\[
\frac{R - M \beta^{\ell+\mu-\text{exp}}}{Y + M \beta^{\ell+\mu-\text{exp}}} < \frac{R_{\text{frac}}}{Y_{\text{ff}}} \beta^{\mu-\text{exp}} \leq \frac{R}{Y}
\]

From \( \beta^\ell \leq M < \beta^{\ell+1} \) we obtain,
\[
\frac{R - \beta^{\ell+\mu-\text{exp}}}{Y + \beta^{\ell+\mu-\text{exp}}} < \frac{R_{\text{frac}}}{Y_{\text{ff}}} \beta^{\mu-\text{exp}} \leq \frac{R}{Y}
\]

and,
\[
\frac{R \beta^{\ell+\mu-\text{exp}} - \beta^{\ell+\mu-\text{exp}}}{1 + \beta^{\mu-\text{exp}} - \beta^{\ell}} \geq \frac{R_{\text{frac}}}{Y_{\text{ff}}} \beta^{\mu-\text{exp}} \times Y \geq 0
\]

From \( \nu \geq R_{\text{exp}} + 1 \) and if
\[
Y_{\text{e}} + Y_{\text{exp}} = \nu - 1
\]

(that is possible with two FPL reconstructions) then,
\[
\frac{\beta^{\ell+\mu-\text{exp}} + \beta^{\ell+\mu-\text{exp}}}{1 + \beta^{\ell}} > \frac{R_{\text{frac}}}{Y_{\text{ff}}} \beta^{\mu-\text{exp}} \times Y \geq 0
\]

Thus
\[
\beta^{\ell+\mu-\text{exp}+1} > R - \frac{R_{\text{frac}}}{Y_{\text{ff}}} \beta^{\exp} \times Y \geq 0
\]

As we have,
\[
\frac{R_{\text{frac}}}{Y_{\text{ff}}} \beta^{\exp} \times (1 - \beta^{\mu+1}) < D
\]

\[
\leq \frac{R_{\text{frac}}}{Y_{\text{ff}}} \beta^{\exp} \times Y
\]
Eqn. (12) becomes,
\[
\beta^\ell \cdot R_{\text{exp}} + \frac{R_{\text{exp}}}{Y} D Y \geq 0
\]
\[
\beta^{\ell+2-\mu} R_{\text{exp}} + 1 + R \cdot Y > R - D \times Y \geq 0
\]
\[
\beta^{\ell+\mu} R_{\text{exp}} > R - D \times Y \geq 0
\]
we therefore obtain,
\[
\beta^{\ell+\mu} > R - D \times Y \geq 0 \quad (13)
\]
Thus we have no overflow problems in \( R_{\text{RNS}} \leftarrow R_{\text{RNS}} - Y_{\text{RNS}} \times D_{\text{RNS}} \) because \( R - D \times Y \geq 0 \). And, if \( R_{\text{exp}} + \mu - \ell - 2 < Y_{\text{exp}} \) then the next value of \( R_{\text{exp}} \) can be \( R_{\text{exp}} + \mu - \ell - 2 \), else \( R_{\text{exp}} = Y_{\text{exp}} \). This confirms that \( R_{\text{exp}} \) decreases to \( Y_{\text{exp}} \).

As we have seen in (13), and considering (11) we deduce that just before the last iteration we have \( R < \beta \times Y \) and \( \beta^2 - 1 < D \leq \beta^2 \). Now the last iteration gives from (12),
\[
\beta^{\ell+1} > R - \frac{R}{Y} \geq 0
\]
and (13) becomes,
\[
\beta^{\ell+\mu} + 1 > R - D \times Y \geq 0
\]
in other words for \( \mu > \ell + 1 \),
\[
(\beta^{\ell+1} + 1) \times Y > R - D \times Y \geq 0
\]
\[
2 \times Y > R - D \times Y \geq 0 \quad (14)
\]
This requires at most another iteration with an exact comparison using a Mixed Radix number system.

4.1. Performance
To summarize, each iteration of the division algorithm requires:

- Communications:
  - The computation of \((R_{\text{FPL}}, R_{\text{exp}})\) needs \( \log_2 n \) AU-to-AU communication steps for the construction of \( \sigma \).
  - 2 broadcasts for the transmission of \((D_m, D_e)\) from FPL to AUs

- Computations:
  - at most four \( \mu \)-digit comparisons in the FPL-unit.
  - at most \( \mu \) comparisons and shifts for the evaluation of \( R_0 \) in the FPL-unit
  - four \( \mu \)-digit additions, one \( \mu \)-digit multiplication and one \( \mu \)-digit integer division.
  - at most \( \log_2 n + 1 \) \( \mu \)-digit modular multiplications and \( \log_2 n + 1 \) \( \mu \)-digit table lookups for the computation of the residues \( d_i \) in the AU-units.
  - two \( \mu \)-digit modular additions and one \( \mu \)-digit modular multiplication for the evaluation of \( R_{\text{RNS}} \) and \( Q_{\text{RNS}} \) in the AU-units.
  - one \( \mu \)-digit comparison and one \( \mu \)-digit addition to construct \( R_{\text{exp}} \) in the FPL-unit.

We can therefore assume that the complexity of one iteration is \( O(\log n) \).
The number of steps is at most equal to \( \frac{\mu}{\mu+2} \).
Thus the cost of this loop is \( O(n \log_2 n) \) with a small hidden constant. Finally the last step of our algorithm is done in time \( O(n) \) [5]. This gives the following result.

Theorem 3. The proposed RNS-division algorithm is a \( O(n \log_2 n) \)-time algorithm, with \( O(n) \) space.

5. Other recent algorithms
Comparison and division are difficult problems in RNS arithmetic. Many algorithms have been proposed in the literature to cope with these problems. In 1991 D. Gambperger presented an original RNS division algorithm without comparisons, whose execution time only depends on the value of the divisor [11]. Each iteration requires \( 2 \times n + 3 \) modular steps, and often more than \( \log_2(n) \) iterations. For example with moduli 43, 47, 53, 59 and 61, with a divisor close to \( 10^6 \) the maximum number of iterations is equal to 18. The execution time of our algorithm does not depend on the
value of the divisor, it only depends on the size of the difference between the dividend and the divisor. The worst case of our algorithm has a better execution time than the mean case of Gamberger’s algorithm.

M. Lu and J.S. Chiang proposed an RNS division based on a classical high-radix division algorithm with comparisons performed using a parity checking [13, 14]. To have an efficient $O(n \log(n))$-time algorithm they use $n$ tables. The size of each table is proportional to $m_i \times (\log_2 (n \times M))$. For example, if $\nu = 1024 = 2^{10}$ then the size of the tables is close to $2^{32}$ bits. At each iteration, Lu and Chiang’s algorithm computes a binary digit of the quotient. Thus, as our algorithm computes a radix-2 in digit at each iteration, we must compare one iteration of our method to $\mu - \ell - 2$ iterations of M. Lu and J.S. Chiang’s algorithm. In other words if the $\mu$-digit division is performed faster than $\mu$ additions and $\mu \log(n)$ table look-ups, then we can assume that our algorithm is better. Moreover, our algorithm is not limited by the size of a table.

More recently, Hitz and Kaltofen have proposed an integer division in residue number systems, based on Newton iteration [15]. This algorithm uses an extended base and performs many conversions in a Mixed Radix System (MRS) and base transfers. The MRS conversion uses relation (4) of the CRT proof, that enables a $O(\log(n))$ conversion time rather than the more classical linear algorithm [5]. The computation of (4) is done in MRS with $O(n^2)$ modular adds and an $O(n^2)$-size tree of modular multipliers. This algorithm divides two RNS numbers with an $O(n \log(n))$ time complexity. The size complexity of our algorithm is $O(n)$ and enables the division of huge numbers (say, more than 1000 bits) in time $O(n \log(n))$.

6. Conclusion

We have proposed an efficient algorithm for RNS division, the implementation of which is realistic. This algorithm is suited for the manipulation of huge numbers. The execution time of this algorithm is better than that of previously published algorithms, and it does not require large tables. We do not claim that our algorithm is attractive for applications such as computer cards — e.g., credit cards or phone cards — for such applications, other algorithms (see for instance [18]) looks more promising. The use of our algorithm to perform modular multiplications of huge numbers (i.e., a RNS multiplication followed by a RNS division) would be comparable to the use of modular multiplication algorithms proposed by N. Takagi [19, 18] or P. Kornerup [20] as soon as $\mu > \log_2 n$.
